Abstract

Considering both size and dimensions of the offshore wind turbine structures, design optimization of such structures is a fruitful yet, simultaneously, onerous task due to the tempestuous complexity of the problem, which mostly comes from their environment. However, in this study, a computerized methodology based on meta-heuristic algorithms, consisting of the Colliding Bodies Optimization (CBO), Enhanced Colliding Bodies Optimization (ECBO), and Vibrating Particle System (VPS), is presented such that more economic upshots can be accomplished. Hence, minimization of the total weight of the structure subjected to a number of structural constraints, including a frequency constraint, by applying the above mentioned algorithms is the underlying goal of this study. Using the data from Horns Rev I offshore wind farm, which is located in the coastlines of Denmark in the North Sea, this study is performed based on a simplified structural model of a monopile offshore wind turbine structure, which can be utilized in preliminary stages of pertinent projects for conducting suitable comparisons.

KEYWORDS: Offshore wind turbines, monopile supporting structures, engineering optimization, structural design optimization, meta-heuristic algorithms

1. Introduction

Significant increase in the population throughout the world and outstanding abatement in fossil fuel resources unearth the importance of supplanting the role of fossil fuels in supplying worldwide energy demands with new resources such as renewables. Considering the fact that wind is envisaged to be one of the most promising resources among renewables, wind turbines have engrossed so many attentions in recent years. In the past, the application of wind as an energy resource was solely materialized in onshore wind turbines. Although many advantages have been presented using this
approach, there are some hurdles hindering its application, including both visual and noise pollutions. Moreover, substantial land occupancy of onshore wind turbines due to the noteworthy reduction in available lands near populated regions may additionally lead toward a remarkable increase in required capitals. To overcome the mentioned barriers, offshore wind turbine concept was proposed. Increasing investments on offshore wind turbine industry, not only may the abovementioned problems be omitted, but also reaching noticeably longer and stronger wind resources have become viable, which has resulted in stronger reliance on such assets in some European countries such as United Kingdom as well as Germany [1].

Given two main categories of structural systems utilized in offshore wind industry, bottom-fixed and floating support structures, the application of the former was commenced using monopiles. The popularity of these supporting structures can be revealed considering the fact that more than 65 percent of installed offshore wind turbines enjoy a monopile as their supporting structure. This popularity mostly come from outstanding simplicity in both their design and production stages [2].

Higher potential of offshore wind resources has resulted in a noticeable increase in the size of offshore wind turbines compared to onshore wind structures; hence, design optimization of such structures would be an indispensable mission by which the required capitals may be substantially cut [3]. To do so, many approaches have been presented, which can be mainly categorized in two fundamental groups: (i) Local optimizers; (ii) Global optimizers. Local optimizer algorithms mostly employ gradient information or iterative methods in order to run an exploration within the solution space in the periphery of an initial point for obtaining better outcomes. The major disadvantages of the aforementioned method may be stated as both significant hardship in implementation and the required time. Consequently, global optimizers such as meta-heuristic algorithms are proposed [4-5]. Several number of these algorithms have recently been developed based on mimicking natural phenomena [6-7] and applied to optimization of challenging problems [8-15]. The main advantages of meta-heuristic algorithms are simplicity in implementation and less time-consumption.

Nevertheless, this research is performed based on three meta-heuristic algorithms; Colliding Bodies Optimization (CBO), Enhanced Colliding Bodies Optimization (ECBO), and Vibrating Particle System (VPS). Colliding Bodies Optimization (CBO) is a population-based meta-heuristic algorithm, developed by Kaveh and Mahdavi [5], which attempts to mimic governing laws in collision between bodies. Palpable plainness in formulation and parameter independency are the main features of this algorithm. Enhanced Colliding Bodies Optimization (ECBO), which was introduced by Kaveh and Ilchi Ghazaan [16], utilizes a memory in order to enhance the CBO performance by saving some historically best solutions, which results in better performance in escaping from local minima without any increase in the computational cost. Vibrating Particle System (VPS) is a recent-developed meta-heuristic algorithm introduced by Kaveh and Ilchi Ghazaan [7]. The damped free vibration of single degree of freedom systems inspires this population-based meta-heuristic algorithm. It treats each solution candidate as a particle that seeks its equilibrium position.

Based on what is mentioned so far, this study is aimed to indicate how meta-heuristic algorithms can be applied in preliminary design optimization of a monopile offshore wind turbine structure while considering some structural constraints. To do so, firstly a simplified model of such structures is introduced. Given the environmental load cases being applied on offshore structures such as wave and wind loadings, the model is then analyzed using Finite Element Method by which internal stresses and nodal displacements can be subsequently determined. Fulfilling considered constraints, the mentioned algorithms are utilized striving to discern the lowest possible weight for the structural elements while
meeting all constraints. It should be mentioned that all steps of this study including modeling, loading, analysis and optimization of the structure are established and developed using MATLAB.

2. Configuration of a Monopile Offshore Wind Turbine Structure and its Simplified Model

Monopile offshore wind turbine structures are surmised to be the simplest option in offshore wind industry. This type of offshore wind structures regularly comprises of a cylindrical pile penetrating in the seabed, a transition piece that connects tower to the monopile, and typical components of each wind turbine such as nacelle, hub, rotor and blades [2].

Since the main objective of this study is to provide a preliminary design optimization of monopile offshore wind turbine structures, a simplified model is therefore defined based on following assumptions:

- All the external equipment including cables, ladders or working platforms, whether connected to the structure or not, are neglected.
- The transition piece is completely ignored in this study. In fact, considering the crucial role of transition piece in both structural integrity and structural performance of monopile structures, its special characteristics must be investigated according to a detailed study; thus, in this research, the transition piece is considered being made of a linear, elastic, and isotropic material, with same structural properties as the whole structure.
- It is assumed that the structure is completely clamped at the bottom, meant for ignoring the soil-structure interaction. In other words, the penetration length of the monopile in the seabed soil is considered zero.

Monopile offshore wind turbine structures normally consist of a pile with constant diameter and a tapered tower in which the cross-section is continuously decreased from the bottom to the top of the structure. In this study, however, the whole structure is considered as a stepped tower. It means that the structure is made of several cylindrical circular segments with abrupt changes in sections [17]. In fact, the height of each segment is pre-defined and optimization algorithms are deployed having both diameter and thickness of each section as the design variables.

3. Applied Loads on the Structure and Pertinent Codes

3.1. Design Standards and Underlying Principles

All the environmental forces imposed on the structure, such as wind and wave actions, are assessed based on DNV standard in this study [18-19]. DNV standard is coded in accordance with partial safety factor method, satisfied under a linear combination of applied load cases on structures.

Given the limit state concept, offshore wind turbines must comply with following states:

- **Ultimate Limit State:** Failure of structures due to the paucity of sufficient capacity in bearing actions under miscellaneous load combinations.
- **Serviceability Limit State:** Lack of capability in structures working properly.
- **Fatigue Limit State:** Failure of structures because of cyclic loads fatigue.
- **Accidental Limit State:** Failure of structures because of the accidents like vessel impacts.
Given the aforementioned limit states, ultimate and serviceability limit states are the only states taken into account in further the steps of present research.

3.2. Applied Load Cases

Wind turbines are of the most complex structures, which must resist several load cases including wind, earthquakes, gravity loadings, and, additionally, those that come from the operation of the wind turbine (Fig. 1) [2]. Not only must an offshore wind turbine structure remain stable under several combinations of mentioned actions, but also hydrodynamic loads, which emanate from different sources such as waves, currents etc., are also applied on such structures. In fact, these effects cause more complexity in both analysis and design of offshore wind turbine structures compared to onshore wind turbines. In this study, however, succeeding load cases are the only ones taken into account:

- **Permanent Load Cases:** These loads are constant and invariable in any arbitrary design period. Wind turbine weight, tower weight, transition piece weight, and monopile weight are the most important permanent loads that are taken into consideration in present research.
- **Environmental Load Cases:** Numerous number of natural phenomena can affect the integrity of an offshore wind turbine structure such as earthquakes, temperature, snow, ice, etc. In this study, however, wave, both wind-generated and tidal currents, and wind are the only considered environmental actions.

Quantification of aforementioned environmental actions are briefly described in following subsections.

3.2.1. Wave Loading

In this study, quantification of the wave action is carried out using well-known Morrison equation, which is a combination of theory and empiricism. It must be borne in mind that this equation is only applicable in the cases in which the dimension of the monopile is small compared to wavelength ($D < 0.2\lambda$). Considering the typical wavelength of ocean waves, this stipulation is regularly met [2].

Based on Morrison equation, the total hydrodynamic load per unit length of a slender element consist of two terms, drag and inertia, which can be stated as follows [2]:

$$dF = dF_m + dF_d = \frac{C_m \pi D^2}{4} \rho u_w dz + \frac{C_d \rho D}{2} |u_w| u_w dz$$  \hspace{1cm} (1)

Where:

- $dF_m$: Inertia force (N/m)
- $dF_d$: Drag force (N/m)
- $C_m$: Inertia coefficient
- $C_d$: Drag coefficient
- $D$: Element diameter (m)
\( \rho \): Mass density of sea water (kg/m\(^3\))

\( u_w \): Horizontal velocity of water particle (m/s)

\( \dot{u}_w \): Horizontal acceleration of water particle (m\(^2\)/s)

Both drag and inertia coefficients are functions of relative roughness, Reynolds, and Keulegan-Carpenter numbers, which can be determined based on DNV standard [18]. In this study, these parameters are taken as 0.7 and 2, respectively.

Next step is to find water particles kinematics. In order to assess horizontal velocity and acceleration of water particles, linear wave theory is employed (Fig. 2). Based on linear wave theory, horizontal water particle kinematics are described as follows [2]:

\[
 u_x = \omega \zeta_a \frac{\cosh k (h + z)}{\sinh kh} \cos (kx - \omega t) \tag{2}
\]

\[
 a_x = \omega^2 \zeta_a \frac{\cosh k (h + z)}{\sinh kh} \sin (kx - \omega t) \tag{3}
\]

Where:

\( \omega \): Angular frequency (Rad/s)

\( \zeta_a \): Wave amplitude (m)

\( k \): Wave number

\( h \): Water depth (m)

\( z \): Desired depth (m)

It must be mentioned that since linear wave theory is only applicable up to the still water level (\( z=0 \)) and the wave kinematics of the upper levels are not established using this theory, Wheeler stretching approach is utilized for handling this problem [2]. Based on this model, vertical coordinate must be superseded with the scaled coordinate, which is stated below [2]:

\[
 z' = (z - \zeta) \frac{h}{h + \zeta} \tag{4}
\]

Where:

\( \zeta = \zeta_a \cos (kx - \omega t) \): Instant wave elevation

**3.2.2. Current Loading**

Two types of currents are basically considered when assessing environmental loads imposed on offshore wind turbine structures, including both wind-generated and tidal currents, which are evaluated according to [18] as follows:
\[ v(z) = v_{\text{tide}}(z) + v_{\text{wind}}(z) \]  
\( (5) \)

\[ v_{\text{tide}}(z) = v_{\text{tide}0} \times \left( \frac{h + z}{h} \right)^{1/7} \]  
\( (6) \)

\[ v_{\text{wind}}(z) = v_{\text{wind}0} \times \left( \frac{h_0 + z}{h_0} \right) \]  
\( (7) \)

\[ v_{\text{wind}0} = k \times U_0 \]  
\( (8) \)

Where:

- \( k \): 0.015 to 0.03
- \( U_0 \): 1-hour mean wind speed at 10 m height (m/s)
- \( h \): Water depth (m)
- \( h_0 \): Reference depth from wind generate current (50 m)
- \( v_{\text{wind}0} \): Wind generated current at still water level (m/s)
- \( v_{\text{tide}0} \): Tidal current at still water level (m/s)
- \( z \): Vertical coordinate from still water level (m)

In order to take the current loading into account, the current velocities must be incorporated in evaluating the drag term of Morrison equation [20].

\[ F_d = \frac{1}{2} C_d \times \rho \times D \times \left( |u + U_c| \right) \times (u + U_c) \]  
\( (9) \)

Where:

- \( u \): Horizontal water particle velocity (m/s)
- \( U_c \): Current velocity (m/s)

### 3.2.3 Wind Loading

#### 3.2.3.1 Wind Force on Tower

According to DNV standard, wind force on the structural elements of wind turbine towers can be found using subsequent formula [18]:
\[ F = \frac{1}{2} \times \rho_a \times C_S \times S \times U^2 \] (10)

Where:
\( \rho_a \) : Air density (kg/m\(^3\))
\( C_S \) : Shape coefficient
\( S \) : Projected area of the member normal to the direction of the force (m\(^2\))
\( U \) : Wind velocity (m/s)

Note that Shape coefficient in this study is considered 0.7. Additionally, given the wind conditions described in DNV standard - Normal Wind Condition and Extreme Wind Condition - since considering Extreme Wind Condition result in more severe forces in the structure, this scenario is adopted for assessing wind actions in this study [21].

Wind inherently is a dynamic phenomenon. It indicates that not only is wind velocity altered in different altitudes, but also velocities recorded by an anemometer in a certain height vary with time. Considering abovementioned fact, quantification of wind velocity under Extreme Wind Condition can be carried out using following formulas [18]:

\[ C = 5.73 \times 10^{-2} \times \sqrt{1 + 0.15 \times U_0} \] (11)

\[ I_U = 0.06 \times (1 + 0.043 \times U_0) \times \left( \frac{z}{h} \right)^{-0.22} \] (12)

\[ U(T,z) = U_0 \times \left[ 1 + C \times \ln \left( \frac{z}{h} \right) \right] \times \left[ 1 - 0.41 \times I_U \times \ln \left( \frac{T}{T_0} \right) \right] \] (13)

Where:
\( U_0 \) : 1-hour wind mean speed at 10 meter height (m/s)
\( h \) : 10 meter
\( T_0 \) : 3600 second
\( T < T_0 \) : Desired time (s)
\( z \) : Desired height from still water level (m)

3.2.3.2. Wind Force on Rotor and Blades

Modern wind turbines are equipped with some control systems by which power production rate and wind loads on the structure can be controlled so that the occurrence of tentative damages due to the increment in wind velocity and, subsequently, wind force can be prevented. In fact, these systems
are directly responsible for establishment of both start-up and shutdown commands in wind turbines when reaching the cut-in and cut-out wind speeds, respectively. Indeed, the operation of wind turbines is entirely ceased if the current wind speed exceeds cut-out wind limit [2]. Since the stopped mode does obviously result in more severe forces in comparison with the operation mode, aerodynamic forces are evaluated based on this mode in this study. In this case, the most unfavorable position of blades is depicted in (Fig. 3) [21]. Based on Blade Element Theory, drag and lift forces in each blade can be determined as follows (Fig. 4) [20]:

\[
F_L = \frac{1}{2} \times C_L(\alpha) \times \rho_{\text{air}} \times V_{\text{rel}}^2 \times c_a \times \Delta r \tag{14}
\]

\[
F_D = \frac{1}{2} \times C_D(\alpha) \times \rho_{\text{air}} \times V_{\text{rel}}^2 \times c_a \times \Delta r \tag{15}
\]

\[
V_{\text{rel}} = \sqrt{V_{\text{Disk}}^2 + V_{\text{Rot}}^2} \tag{16}
\]

\[
a = \frac{V_0 - V_{\text{Disk}}}{V_0} \tag{17}
\]

\[
V_{\text{Rot}} = \Omega \times r \tag{18}
\]

Where:

- \( F_L \): Aerodynamic lift (N)
- \( F_D \): Aerodynamic drag (N)
- \( C_L(\alpha) \): Aerodynamic lift coefficient
- \( C_D(\alpha) \): Aerodynamic drag coefficient
- \( \rho_{\text{air}}(\alpha) \): Mass density of air (kg/m\(^3\))
- \( c_a \): Airfoil chord length (m)
- \( \Delta r \): Radial length of blade element (m)
- \( \alpha \): Angle of attack (deg)
- \( \Omega \): Angular rotational speed (rad/s)
- \( V_0 \): Upstream wind velocity (m/s)
- \( V_{\text{Disk}} \): Wind velocity at airfoil (m/s)
- \( \alpha \): Induction factor
- \( r \): Distance of blade element to axis of rotation (m)

Finally, total load in x-direction in each blade can be calculated as [20]:
\[ F_x = F_L \cos \phi + F_D \sin \phi \]  
(19)

\[ V_{ax} = N_b \sum_{r=\text{tip}}^{\text{root}} F_{x,r} \]  
(20)

The moment acting on the top of the structure can be then found satisfying equilibrium of moments.

3.3. Load Combinations

By making an assumption indicating that changes in wave and wind forces do not have any correlations, linear combination approach can be adopted when combining miscellaneous load cases. DNV standard describes following load combinations for designing wind turbine structures under Ultimate Limit State. Note that serviceability limit state criteria must be fulfilled under a load combination in which all the coefficients of different load cases are considered as unity [21].

First Load Combination: dead load (containing self-weight of the whole structure including tower weight, pile weight, and wind turbine weight multiplied by a coefficient equal to 1.25)+wind load (consisting of both imposed wind load on tower and turbine multiplied by a coefficient equal to 0.7)+wave load (multiplied by a coefficient equal to 0.7)

Second Load Combination: dead load (containing self-weight of the whole structure including tower weight, pile weight, and wind turbine weight multiplied by a coefficient equal to 1)+wind load (consisting of both imposed wind load on tower and turbine multiplied by a coefficient equal to 1.35)+wave load (multiplied by a coefficient equal to 1.35)

4. The Monopile Offshore Wind Turbine Structure Optimization Problem

4.1. Optimization Problem

A typical structural optimization problem can be stated as follows [4]:

Find \( X = [x_1, x_2, x_3, x_4, \ldots, x_n] \)

To minimize \( \text{Mer}(X) = f(X) \times f_{\text{penalty}}(X) \)

Subjected to \( g_i(X) \leq 0, i = 1, 2, \ldots, m \)

\( x_{i,\text{min}} \leq x_i \leq x_{i,\text{max}} \)

Where \( X \) is the vector of design variables with \( n \) unknowns, \( g_i \) is the \( i\text{th} \) constraint from \( m \) inequality constraints. For the sake of simplicity, in this study, well-known penalty approach is adopted for constraint handling, where \( \text{Mer}(X) \) is the merit function, \( f(x) \) is the cost function, and \( f_{\text{penalty}}(X) \) accounts for constraint violations. Additionally, the values of design variables are restricted to \( x_{i,\text{min}} \) and \( x_{i,\text{max}} \), being the lower and upper bounds of variables, respectively. In present research, following penalty function is used to transform a constrained optimization problem into an unconstrained one:
\[ f_{\text{penalty}}(X) = \left(1 + \varepsilon_1 \sum_{i=1}^{m} \max(0, g_i(X)) \right)^{\varepsilon_2} \]

(22)

The parameters \( \varepsilon_1 \) and \( \varepsilon_2 \) in the penalty function are chosen considering both exploration and exploitation rates within search space in algorithms. The parameter \( \varepsilon_1 \) in the utilized penalty function is chosen as unity. In addition, \( \varepsilon_2 \) is selected 1.5 at the start and linearly increased to 3 in the first approach and 10 in the second one, respectively.

4.2. Design Variables

As mentioned, both diameter and thickness of each part of the structure are considered as the design variables in the present research.

\[ X = [D_1, D_2, \ldots, D_n, t_1, t_2, \ldots, t_n] \]

(23)

Therefore, it can be conceived that the design variable vector consists of \( 2n \) variables, where \( n \) is the number of segments. Furthermore, note that \( D_i \) and \( t_i \) are the diameter and thickness of \( i \)th part, respectively.

4.3. Design Constraints

Generally, design constraints can be categorized into many different groups such as serviceability, stability and stress constraints. In this study, two different design constraints are considered for controlling serviceability of the structure, while same number of those are aimed to be controlling both local and global stability of the structure. Finally, internal stresses in different sections of the structure are assessed and controlled with their capacity as the stress constraint.

As the first serviceability design constraint, the fundamental frequency of the structure is assessed and controlled with the recommended values. Since monopile offshore wind turbine structures are sensitive to dynamic excitations due to their slenderness and the nature of their environment, only by restricting dynamic behavior of such structures may the occurrence of unwilling phenomena such as resonance be precluded. The soft-stiff range determined in the (Fig. 5) is presumed to be the best gamut in which the fundamental frequency of offshore wind turbine structures can be accommodated, where “1P” frequency represents the rotational frequency of turbine in the operation mode and “3P” denotes the blade-passing frequency, accounting for shadowing effects. The former mostly takes place between 0.17-0.33 Hz and the latter for a turbine with three blades usually happens between 0.5 Hz up to 1 Hz. This desired interval in this study is assumed to be within 0.32-0.54 Hz [21-22].

Note that, in this study, two different structural approaches are utilized for finding the fundamental frequency of the structure. As the first approach, the structure is reduced into a simplified 2D dynamic model in which each segment is considered as a frame element. Each node of these elements contains 3 degrees of freedom: one horizontal translation, one vertical translation and one planar rotation. The mass matrix of each segment is then obtained using consistent mass formulas. The mass and the stiffness matrices of the entire structure are subsequently accomplished using an assembling approach [17].
As the other approach, the fundamental frequency of the structure is simply calculated using the following estimation [20]:

\[
 f_{nat}^2 = \frac{3.04}{4\pi^2} \times \frac{EI}{\left(0.227 \times \mu \times L + m_{top}\right) \times L^3}
\]  

(24)

Where:

- \( f_{nat} \): Fundamental frequency (Hz)
- \( m_{top} \): Turbine mass (kg)
- \( \mu \): Structure mass per meter (kg/m)
- \( L \): Structure length (m)
- \( EI \): Tower bending stiffness (N.m^2)

It must be borne in mind that in this approximation, since the simplified model contains several segments with different diameters and thicknesses, as a conservative assumption, bending stiffness of the structure is determined using averaged diameter and thickness.

Dynamic effects of vortex shedding are also taken into account in this study. Coincidence of the fundamental frequency of the structure with the frequency of shedding vortices may result in resonance, which must be prevented. To do so, following constraint inequality must be fulfilled [23-24]:

\[
 U_{Cr} \leq 0.2 \times U_{project}
\]  

(25)

Where:

- \( U_{Cr} \): Critical wind velocity (m/s)
- \( U_{project} \): Project wind velocity (m/s)

The critical wind velocity is approximately obtained using the following formula [23-24]:

\[
 U_{Cr} = f \times \frac{D}{S_t}
\]  

(26)

Where:

- \( f \): Natural frequency of the structure (Hz)
- \( D \): Element diameter (m)
- \( S_t \): Strouhal number, which is taken as 0.2 in this study.
The second serviceability constraint is aimed to be restricting the amount of lateral displacement at the top of the tower, which may hinder the performance of wind turbine. This displacement must be limited to less than one percent of the total length of the structure in accordance with DNV [21].

Next set of design constraints are to control the stability of the structure in both local and general scales. These constraints are developed based on Eurocode 3 [25]. To be ensured that local instability will not take place, the following inequality must be fulfilled in all sections. Global stability is also controlled complying with EC3 [25].

$$\frac{D_i}{t_i} \leq 90$$ \hspace{1cm} (27)

Conclusively, the next design constraint states that the summation of axial and bending stresses in all sections could not exceed the yield strength of the utilized steel, which is described as follows [25]:

$$\frac{N_{Ed}}{A} + M_{Ed} \times y \leq \sigma_y$$ \hspace{1cm} (28)

4.4. Cost Function

Cost function or the total weight of structure is established below:

$$f (X) = \sum_{i=1}^{n} \rho g V_i = \sum_{i=1}^{n} \rho g A_i L_i = \sum_{i=1}^{n} \rho g (\pi D_i t_i L_i)$$ \hspace{1cm} (29)

5. Utilized Meta-heuristic Algorithms

Given the complexity of loading and design constraints of offshore wind turbine structures, design optimization of such structures is an expensive task. To overcome this hurdle, in present research, three simple yet efficient meta-heuristic algorithms so-called Colliding Bodies Optimization, Enhanced Colliding Bodies Optimization, and Vibrating Particle System are used to cover the required demands. The abovementioned algorithms are briefly introduced here.

5.1. Colliding Bodies Optimization Algorithm

Colliding Bodies Optimization (CBO) is a recently developed meta-heuristic algorithm that mimics the momentum and energy conservation laws in one-dimensional collision between bodies. This algorithm is a multi-agent algorithm containing a number of Colliding Body (CB) with determined mass and velocity [5]. After collision, CBs move toward new positions, having new velocities in correspondence to old velocities, masses and coefficient of restitution. The algorithm is initialized by random selection of agents within the search space. Sorting agents in accordance with the values of cost function in an ascending manner, CBs are then divided into two equal categories named stationary and moving groups (Fig. 6). Good agents in accordance with the objective function are considered as stationary agents, whose velocities before collision is considered equal to zero. The members of moving category move toward stationary ones before occurrence of the collision. The collision happens in a way that the better and worse CBs collide together, which results in improving
moving CBs positions, simultaneously, with forcing stationary CBs toward better locations. Velocity of the CBs before collision is considered as the value of change in the body position [5].

\[ v_i = 0, \quad i = 1,2,\ldots,n \]

\[ v_i = x_i - x_{i-n}, \quad i = n+1,n+2,\ldots,2n \]  

(30)

Afterward, momentum and energy conservation laws are employed for finding the velocities of each body after collision.

\[ v'_i = \frac{(m_{i+n} + \varepsilon m_{i+2n})v_{i+n}}{m_i + m_{i+n}}, \quad i = 1,2,\ldots,n \]

\[ v'_i = \frac{(m_i - \varepsilon m_{i-n})v_i}{m_i + m_{i+n}}, \quad i = n+1,n+2,\ldots,2n \]  

(31)

In the abovementioned formulas, \( v_i \) and \( v'_i \) are the velocities of the \( i^{th} \) CB before and after collision, respectively. Additionally, the mass of each CB is determined as follows:

\[ m_k = \frac{1}{\sum_{i=1}^{n} \text{fit}(i)} \text{fit}(k), \quad k = 1,2,\ldots,2n \]  

(32)

Where \( \text{fit}(i) \) is the value of objective function for the \( i^{th} \) agent. It can be concluded that good and bad CBs carry larger and smaller masses, respectively. Replacing \( \text{fit}(i) \) with its adverse result in maximization of the objective function using same algorithm. Coefficient of restitution (\( \varepsilon \)), which is defined as the ratio of separation velocity of two agents after collision to approach velocity of two agents before collision, is mostly responsible for controlling the rate of exploration and exploitation in the algorithm, defined as follows:

\[ \varepsilon = 1 - \frac{\text{iter}}{\text{iter}_{\text{max}}} \]  

(33)

Where \( \text{iter} \) and \( \text{iter}_{\text{max}} \) are the actual iteration number and the maximum number of iterations, respectively. Finally, new position of CBs can be determined using following formulas:

\[ x_i^{\text{new}} = x_i + \text{rand} \cdot v'_i, \quad i = 1,2,\ldots,n \]

\[ x_i^{\text{new}} = x_{i-n} + \text{rand} \cdot v'_i, \quad i = n+1,n+2,\ldots,2n \]  

(34)

The optimization process is terminated when reaching a predefined evaluation number such as maximum number of iterations.

5.2. Enhanced Colliding Bodies Optimization Algorithm

To improve the CBO performance, Enhanced Colliding Bodies Optimization is developed utilizing memory in order to save some historically best CBs, which results in obtaining better
solutions consuming less time. Additionally, a mechanism is defined to change some components of CBs randomly to afford a chance for the CBs to escape from local minima and prevent probable premature convergence. This algorithm is mentioned as follows [16]:

**Level 1: Initialization**

**Step 1:** The initial positions of all the colliding bodies are randomly determined within the search space.

**Level 2: Search**

**Step 1:** Each CB need to be assigned a mass value based on Eq. 32.

**Step 2:** Colliding Memory (CM) is then used to save a number of best-so-far vectors and their related mass and objective function values. Solution vectors that are saved in CM are added to the population, and, consequently, the same number of the current worst CBs are discharged from the population. Afterward, CBs are sorted based on their corresponding objective function values in an increasing order.

**Step 3:** CBs are divided into two equal groups: (i) stationary group, and (ii) moving group.

**Step 4:** The velocity of moving CBs before collision is calculated in this step using Eq. 30. Note that the velocity of stationary CBs before collision is zero.

**Step 5:** The velocities of both stationary and moving bodies after collision are then calculated using Eq. 31.

**Step 6:** Eq. 34 determines the new position of each CB after collision.

**Step 7:** In order to escape from local minima, a parameter called Pro is defined within (0,1) which specifies whether a component of each CB must be changed or not. For each colliding body, Pro is compared with \( r_{n_i} \) (i=1,2,…, n), which is a random number uniformly distributed within (0,1). If \( r_{n_i} < \text{Pro} \), one design variable of \( i^{th} \) CB is selected in random and its value is regenerated using subsequent formula:

\[
x_{ij} = x_{i, \text{min}} +  \text{random} \times ( x_{j, \text{max}} - x_{j, \text{min}} )
\]

(35)

Where \( x_{ij} \) is the \( j^{th} \) design variable of the \( i^{th} \) CB, and \( x_{j, \text{max}} \) and \( x_{j, \text{min}} \) are the upper and lower bounds of the \( j^{th} \) variable, respectively. To protect the structure of CBs, only one dimension is altered.

**Level 3: Terminal Condition**

**Step 1:** The optimization process is ceased when reaching a predefined maximum evaluation number.

5.3. Vibrating Particle System Algorithm

The Vibrating Particle System is a meta-heuristic algorithm which is developed based on the free vibration of single degree of freedom systems with viscous damping. This algorithm comprises of a number of particles, which are randomly chosen within an n-dimensional search space, gradually approaching their equilibrium positions [7]. The steps involved in this algorithm are as follows:
Step 1: The VPS parameters are chosen, and the initial positions of all particles are randomly selected in an n-dimensional search space.

Step 2: The objective function is calculated for each particle.

Step 3: Three equilibrium positions toward which each particle is inclined to approach are defined with different weights: (i) the best position achieved so far among the entire population (HB), (ii) a Good Particle (GP), and (iii) a Bad Particle (BP). To determine GP and BP for each candidate, the current population is ascendingly sorted in accordance with their objective function values, and then GP and BP are randomly chosen from the first and second halves, respectively [7].

Additionally, In order to model the effect of damping in algorithm, a descending function, which is commensurate with the number of iterations, is proposed as follows:

\[ D = \left( \frac{\text{iter}}{\text{iter}_{\text{max}}} \right)^{-\alpha} \]  

(36)

Where \( \text{iter} \) is the current iteration number, \( \text{iter}_{\text{max}} \) is the total number of iterations, and \( \alpha \) is a constant number.

Based on the proposed concept (free vibration of single degree of freedom systems), the positions are updated using following formulas:

\[
x_i^j = w_1 \left[ D \cdot \text{rand} \cdot 1 + \text{HB}^j \right] + w_2 \left[ D \cdot \text{rand} \cdot 2 + \text{GP}^j \right] + w_3 \left[ D \cdot \text{rand} \cdot 3 + \text{BP}^j \right]
\]

(37)

\[
A = \left[ w_1 \left( \text{HB}^j - x_i^j \right) \right] + \left[ w_2 \left( \text{GP}^j - x_i^j \right) \right] + \left[ w_3 \left( \text{BP}^j - x_i^j \right) \right]
\]

(38)

\[
w_1 + w_2 + w_3 = 1
\]

(39)

Where \( x_i^j \) is the \( j^{th} \) variable of particle \( i \); \( w_1, w_2, \) and \( w_3 \) are the parameters measuring the relative importance of HB, GP, and BP, respectively. \( \text{Rand1}, \text{Rand2}, \) and \( \text{Rand3} \) are numbers randomly distributed within (0,1). Additionally, a parameter called \( p \) is randomly defined within (0,1) specifying whether the effect of BP must be considered when updating particles or not. It is compared with a random number (\( \text{rand} \)) which is distributed randomly within (0,1). If \( p < \text{rand} \), then \( w_3 \) is considered zero and \( w_2 = 1 - w_1 \) [7].

Step 4: As the process proceeds, particle seeks better results within the search space. When violating a constraint, the corresponding component must be regenerated using harmony search-based side constraint-handling approach.

Step 5: Steps 2 to 4 are repeated until fulfilling a termination criterion such as the maximum number of iterations.

6. Design Example and Results

6.1. Design Example
The present study is performed based on a simplified model of monopile offshore wind turbine structures constructed in coastlines of Denmark in the North Sea as members of the Horns Rev I offshore wind farm [21]. The required characteristics can be found in Table 1.

The design example is considered as a 83.5 meter-high tower, being made of a steel with structural properties as $f_y = 235 \text{ Mpa}$, $E = 2 \times 10^5 \text{ Mpa}$ and $\rho = 7885 \text{ kg/m}^3$, whose height divided into 21 parts including six two-meter high, a one point five-meter high and 14 five-meter high parts from the bottom to the top of the structure, respectively. Thus, the height vector of the design example can be written as follows:

$$H = \{H_1, H_2, \ldots, H_{21}\} = \{2,2,2,2,2,1.5,5,5,5,5,5,5,5,5,5,5,5,5,5,5\} \text{ m}$$ \hspace{1cm} (40)

6.2. Loading

6.2.1. Gravity Loads

The weight of the original structure before optimization can be determined referring to [21], considering same assumptions as this study, which is indicated in Table 2. In addition, Environmental applied loads on the structure are calculated in accordance with the meta-ocean data of the location shown in Table 3.

6.2.2. Hydrodynamic Loading

To assess hydrodynamic loads, following assumptions are made:

- In assessing hydrodynamic loads using Morrison equation, it is assumed that both drag and inertia terms simultaneously take place.
- Hydrodynamic loads are evaluated based on the maximum wave height resulting in the worst scenario.
- It is believed that the phase angle $\pi/4$ yields in more severe forces. Hence, all the hydrodynamic actions are assessed in this phase angle [21].

Note that the density of water for assessing hydrodynamic loads are considered 1025 kg/m$^3$, wherever it is needed.

6.2.3. Aerodynamic Loading

As mentioned, aerodynamic forces in this study are calculated considering the stopped mode under Extreme Wind Condition. The blades of this wind turbine are presumed to be made of NACA-N63-212 airfoil due to lack of information (Fig. 7); thus, the drag and lift coefficients can be obtained using Fig. 7 [21]. The total force and bending moment acting at the top of the tower are mentioned in Table 4 [21].

6.3. Structural Analysis

Structural analysis in this study is carried out utilizing Finite Element Method approach, in which each segment is considered as a frame element. Due to the complexity in load distribution over the structure, it is simplified into a plain, manageable, uniform distribution over each segment. Following
classical Finite Element Method rules, nodal loads and nodal displacements of the structure can be obtained by which conducting all further steps, including stress analysis, becomes possible.

7. Results and Discussion

Based on what is mentioned so far, in this study, CBO, ECBO, and VPS algorithms are employed for investigation of optimal design of a simplified model of a monopile offshore wind turbine structure as a member of Horns Rev I offshore wind farm. This structure is firstly simplified into a manageable model, having 21 segments with predefined heights, which results in 42 design variables. 20 Colliding Bodies in CBO and ECBO algorithms, and 20 particles in VPS algorithm are utilized for searching the possible minimum weight within the search spaces in a certain number of iterations (1000 iterations). The fundamental frequency of the structure is calculated using two different approaches. As the main approach, this value is obtained using a simplified 2D dynamic model while an approximated formula is utilized as the second approach. The parameter $\varepsilon_1$ in the utilized penalty function is chosen as unity. In addition, $\varepsilon_2$ is selected 1.5 at the start and linearly increased to 3 in the first approach and 10 in the second one, respectively. In this way, in early stages, an appropriate exploration may be conducted seeking better solutions and, as the optimization proceeds, unviable outcomes may be more strongly penalized. In ECBO algorithm, the parameter $\rho$ is considered 0.3 when utilizing both approaches. However, in VPS algorithm, the values of $\alpha$, $p$, $wl$, and $w_2$ are set to 0.15, 80%, 0.3 and 0.3, respectively.

Nevertheless, lower bounds of diameter and thickness as the design variables are chosen as 0.5 and 0.01 m, respectively, while seven and 0.1 m are assumed their upper bounds. Thirty-six different attempts, on aggregate, are made to search for optimal design of the structure using each of the metaheuristic algorithms (CBO, ECBO, and VPS) and both dynamic-analysis and approximated approach. Optimization results of all runs including best weight and corresponding design variables, averaged weight, design constraints value, and rest of statistical indices, such as coefficient of variation, are provided in Table 5 and Table 6. The evolution processes of both cost function and merit function values that are obtained during optimization process are depicted in Figs. 8 up to 19. As noticed, none of the constraints including the frequency one is infringed during optimization.

8. Concluding Remarks

The very first fact that should be noted is that structural optimization of offshore structures and, more specifically offshore wind turbine structures, is a tedious and troublesome mission due to the non-convexity and non-linearity of the problem coming from the simultaneous alterations in applied loads with changes in the cross-sections of the structure. Comparing the outcomes of this study with the total weight of the structure which is reported in [21], which is carried out based on same assumptions as this study, it can be noticed that the total weight of the structure is remarkably decreased while all the desired constraints are fulfilled.

The fundamental frequency of the structure is calculated using two miscellaneous approaches. As the first one, the entire structure is simplified into a simplified 2D dynamic model in which each segment is considered as a frame element with consistent mass. Each node of these elements contains 3 degrees of freedom: one horizontal translation, one vertical translation and one planar rotation. As the other approach, an approximated model that resembles the whole structure with a cantilever beam is utilized. The differences between results can be justified by noting how the stiffness matrix is calculated. In the first approach, the stiffness matrix of the structure is obtained by assembling stiffness matrix of each segment when considering them as a frame element. Nevertheless, the
stiffness of the structure in the second approach is gained using averaged diameter and thickness. As a result, the fundamental frequency of the structure when using the first approach is accomplished near the upper bound of the desired interval, while utilization of the second approach results in frequencies in the vicinity of the lower bound of the interval. Additionally, as expected, the obtained results attest to the superiority and efficiency of VPS over CBO and ECBO. In addition, refereeing to the results, ECBO also works more properly than CBO in this optimization problem.

In summary, optimal design of a simplified monopile offshore wind turbine structure by using Colliding Bodies Optimization (CBO) algorithm, Enhanced Colliding Bodies (ECBO) algorithm, and Vibrating Particle System (VPS) algorithm is presented in this study. CBO is developed based on simulating behavior of bodies when colliding each other. Parameter independency and noticeable simplicity in implementation can be stated as its two main features. Using a memory in order to improve the CBO performance, ECBO also enjoys a mechanism that results in better escape from trapping in local minima in comparison with CBO. VPS algorithm, which involves a number of candidate solution representing the particle system, is developed based on the free vibration of the single degree of freedom systems. Having total weight of the structure and cross-section sizes defined as the objective function and design variables, respectively, optimization process is conducted attempting to minimize the objective function while meeting all design constraints. The fundamental frequency of the structure is calculated using two miscellaneous approaches, 2D dynamic model of the structure and an approximated formula. The former obviously results in upshots that are more pragmatic. The efficiency and applicability of the proposed model is then appraised based on a design example from Horns Rev I offshore wind farm. Comparison between the outcomes reported in [21] and the results of this research, remarkable weight reduction is observed while satisfying all constraints, which attests to proficiency of utilized algorithms.
