ABSTRACT

Because of growing competition in the global markets and the vital role of suppliers in business success, the subject of supplier selection has attracted many researchers and practitioners during the recent years. In addition to the supplier selection, the order quantity discount provided by the suppliers, is considered through a new mixed-integer linear programming (MILP) model involving a manufacturer with multiple products and multiple purchasing items over multiple periods. According to the proposed model, the manufacturer purchases different amount of raw materials from selected suppliers in order to produce different products. Customers' demands are fulfilled by minimizing the total purchase, inventory, production, and transportation costs over a multi-period planning horizon. Since the problem is NP-hard, an efficient genetic algorithm (GA) is used to solve the large-scale real-world instances. The results are compared with results from the exact approach wherever possible in order to investigate the efficiency of the algorithm.

Keywords: Supplier selection, Inventory management, Quantity discounts, Carrier selection, Genetic algorithm.

1. INTRODUCTION

Selecting the best supplier among a large number of suppliers sits on the top of virtually all companies' agendas. In practice, in the increasingly competitive market, indicators such as the offered prices and quality significantly affect the selection of suppliers. The costs of raw materials which were supplied and purchased, comprises more than 50% of all costs [1].

Indeed, there is a strong correlation between the supplier selection problem and other subjects such as inventory management as well as transportation strategies. Regarding the inventory management issues, the decision-making process becomes more complicated when suppliers offer their discount conditions in order to obtain a larger market share which in turn, leads customers to have the benefit of purchasing materials at reduced costs. The subject of quantity discounts has attracted significant attention in the literature over several decades. In the field of supplier selection and order allocation within the supply chain context, some researchers have accounted for the benefits of quantity discounts in their presented models [2-9].

Paying special attention to the logistics and transportation costs by selecting the shipping system properly, play a considerable role in the mentioned area of the study, although considering carrier selection in the supplier selection literature is rare [10-12].

In this study we examine a supply chain seeking to select appropriate suppliers in order to reduce the costs associated with inventory management, production management, and transportation, in a dynamic planning environment. The multi-product MILP model which is developed in this paper, considers the decision variables related to the selection of suppliers, the amount of raw

material purchased from each supplier per period, carrier selection and inventory management policy for each period. Accordingly, the presented model minimizes the total cost of supply chain which includes raw materials, contracts, purchases from the supplier(s), production, storage and carrier selection costs. To the best of our knowledge, considering all these factors simultaneously has not received any attention in the literature. Specifically, we believe our main contribution is to include the procurement of raw materials for present and upcoming production periods based on the discount patterns and converting them to final products while dealing with a variety of raw materials and products with different production plans, within an integrated supplier selection model while the carrier selection is taken into account, as well.

Since the modeling of the lot-sizing problems with above-mentioned assumptions belongs to the family of NP-hard problems [13, 14], an efficient GA is provided. In order to validate the proposed algorithm, it is implemented and analyzed on two data sets incorporating 20 samples, one consisting of small-scale sample problems with obtainable optimal solutions, and the other large-scale ones which their optimal solutions can not be reached through the exact method. A direct comparison is made based on the value of objective function and elapsed runtime.

The remainder of this paper is organized as follows. Section 2 presents a brief review of the existing relevant quantitative approaches related to the supplier selection and order allocation problems along with the solution methods. Section 3 determines the mathematical model and examines its validation on the small-scale examples based on several scenarios. In section 4, the proposed GA is presented and applied on twenty small/large-scale samples and the results are compared with the exact approach. Finally, conclusions and suggestions for the future research are presented in section 5.

2. LITERATURE REVIEW

The supply of inexpensive materials from high-quality sources has great impact on developing successful business strategies. For extensive literature reviews on “supplier selection and decision making”, we can refer to De Boer et al. [15], Ho et al. [16] and Chai et al. [17] consisting of different decision-making techniques such as Multi-Criteria Decision Making (MCDM), Mathematical Programming (MP), and Artificial Intelligence(AI) along with integrated approaches (AHP, ANP, DEA etc.).

Ghodsypour and O’Brien [18] proposed a mixed integer non-linear programming (MINLP) model with multiple sources which consider the net inventory holding price as well as the transportation and ordering costs. Basnet and Leung [19] proposed a supplier selection and an inventory lot-sizing model including multiple products in a multi-period horizon to minimize the purchasing, ordering and inventory holding costs. Liao and Rittscher [10] investigated a nonlinear multi-objective model that includes minimizing the cost of logistics and transportation, defective items and delivery time objectives along with the selected carrier. Rezaei and Davoodi [13] presented two multi-objective mixed integer non-linear programming (MOMINLP) models for multi-period lot-sizing supplier selection problems consisting of multiple products with shortage and non-shortage assumptions. Their objectives were to optimize the cost (purchasing, ordering, holding and transportation), quality, and service level. In another study, they proposed a MINLP model with three objectives of total profit, inconsistency and deficiency [20]. They used NSGA-II to solve their model. Mendoza and Ventura [21] proposed two mixed integer nonlinear programming models to select the best set of suppliers and to determine the proper allocation of order quantities. Their aim was to minimize the annual ordering, inventory holding, and purchasing costs under suppliers’ capacity and quality constraints. Senyigit [22] presented a MILP lot-sizing supplier selection model. His model incorporated a multi-product, multi-echelon defective supply chain network seeking to minimize the total relevant costs. Aliabadi et al. [23] provided an integrated non-linear binary model with multiple items for the supplier selection

problem. In their study, inventory costs for both suppliers and buyers, production costs for suppliers and transportation costs are considered. Ventura et al. [24] provided a multi-period inventory lot-sizing model for a single product in a serial supply chain. The objective of their MINLP model was to minimize the total variable costs including purchasing, production, inventory, and transportation costs. They also considered the all-unit quantity discounts approach for the actual transportation costs.

A stochastic lot-sizing problem with multiple suppliers along with quantity discounts was presented by Kang and Lee [25]. Their multi-objective programming model consisted of cost minimization and service level maximization functions. They used an efficient heuristic dynamic programming model to solve the MILP model. A MINLP model was presented for the order allocation by Meena and Sarmah [8] which considered quantity discounts for potential suppliers solved by a GA approach. In their research, the suppliers are exposed to the risk of failure due to man-made or natural disruptions. Gorji et al. [26] presented a two-level supply chain with one retailer and several suppliers involving multiple periods to determine both supplier selection and inventory allocation policies. Total profit was the objective function of their MINLP model which was solved by GA. Lee et al. [14] provided a MIP model for the lot-sizing supplier selection problem encompassing multiple periods along with all-unit and incremental discounts. They sought to minimize the costs including ordering, holding, purchasing, and transportation via an efficient GA. Choudhary and Shankar [11] represented a single-objective MIP model that considered supplier selection along with carrier selection. They allowed shortage on a single product and used the exact method to solve the model. In their latest research, Choudhary and Shankar [12] presented a goal programming model for inventory lot-sizing with the supplier selection and carrier selection decision process. Their single-product multi-objective integer linear programming (MOILP) approach incorporated the all-unit quantity discounts which were offered by potential suppliers. Cardenas-Barron et al. [27] presented a new reduce and optimize approach to solve the MILP for the multi-product multi-period inventory lot sizing with supplier selection problem solved by a heuristic algorithm. Zaheri et al. [28] proposed two models to formulate a Supplier selection in a single-buyer, multi-supplier two-echelon supply chain network under all-unit quantity discount policy that both buyer and vendor play the leadership role in a bi-level programming model structure. Ghaniabadi and Mazinani [29] presented the single product dynamic lot sizing problem with supplier selection and backlogging in the presence of incremental and all-units quantity discounts. Alfaresa and Turnadi [30] provided a MIP model for a realistic multi-item lot-sizing problem with multiple suppliers, multiple time periods, quantity discounts, and backordering of shortages. In order to tackle larger problem sizes, two heuristic solution methods are proposed including a Silver-Meal heuristic and a problem-specific GA. Suriyan and Rungreunganun [31] present mathematical developments minimizing the total costs of inventory management MILP and supplier selection for inventory lot-sizing problem with quantity discounts with multi-products through multi-periods with the consideration of supplier lead-times and under the conditions of purchasing budgets. Kanchanaruangrong and Woarawichai [32] proposed a multi-product and multi-period inventory lot-sizing problem with supplier selection under vehicle capacity and both all-units and incremental quantity discounts. The buyer's objective of their MILP model was to minimize costs including purchase cost of the products, ordering cost for the suppliers, transportation cost for the suppliers and holding cost of the remaining inventory in each period. Zaheri et. Al [33] aimed to formulate a supply chain with a buyer and multiple suppliers using bi-level programming approach with a hierarchical structure and PSO and Differential Evolution (DE) algorithms were developed to solve their nonlinear bi-level programming problem (NBLP).

Table 1 illustrates a comparison between the present research and other existing studies in this area.

(Table 1 should be inserted here)

In the supplier selection domain, there are a few studies that have simultaneously considered quantity discounts while shipping through the selected carriers. Most of these studies focus on single product mode and do not account for the production constraints. As a result, raw materials and time constraints, which are the most important components in a production process, have not been examined in the literature. The purpose of this study is to support decision makers by providing a MILP model looking to establish a trade-off among inventory holding, production, transportation and procurement process costs, within an all-unit quantity discounts environment.

3. PROBLEM DEFINITION AND MODEL DEVELOPMENT

With the expansion of the competitive atmosphere, it is remarkable that in the real world each manufacturer can satisfy their demands through different suppliers providing different quantity discounts and then carry them using various carriers. According to this, we consider a supply chain containing several suppliers which supply different raw materials and a manufacturer that produces different types of products to fulfill the customers' demands, so that raw materials are transported to manufacturer by different transportation carriers. The total cost is the sum of the purchasing, ordering, production, inventory holding and transportation costs. The solution to the problem determines which raw materials should be ordered, in what quantities, from which supplier(s), by which transportation carrier(s), and during which time periods, so that the customers' demand is satisfied whereas the product shortage is not allowed. There is also the possibility for the manufacturer to take advantage of discounts to purchase raw materials at large volumes and store them to fulfill the customers' demands in the future. Due to the production costs and time constraints in each period, the manufacturer should adopt an efficient policy on purchase quantities in order to reach a cost balance. In the meantime, the costs of shipment between the manufacturer and customers are undertaken by customers; thus, it is not considered in the model. Fig.1 shows the assumed supply chain network.

(Figure 1 should be inserted here)

Other assumptions considered in this study are as follows:

- The demand quantities for multiple products are known but inconstant over the multiple planning periods.
- The price of unit raw material received from suppliers depends on the order quantity in each period. With this in mind all-unit quantity discount is applied.
- Inventory holding costs are known for raw material and product and vary in each period.
- The planning horizon is finite and known. The length of each period is fixed as well.
- Transportation costs depend on the selected carrier(s), which in turn depend on the selected supplier and period.
- The supply capacity of suppliers is finite and different in each period.
- The storage capacity of raw materials and products is finite and different in each period.
- Each carrier has a distinct capacity which is limited.
- The number of available carriers is finite and different in each period.

The notations of the model are presented as follows:

Set indices:

i	the index of the raw materials purchased from the suppliers ($i = 1, 2, \dots, I$)
j	the index of the suppliers ($j = 1, 2, \dots, J$)
k	the index of the all-unit price break levels ($k = 1, 2, \dots, K$)
t	the index of the discrete planning periods ($t = 1, 2, \dots, T$)
l	the index of the transportation carriers ($l = 1, 2, \dots, L$)
p	the index of the products ($p = 1, 2, \dots, P$)

Parameters:

D_{pt}	the total demand of the p -th product in period t
O_{jt}	the cost of placing order to supplier j in period t
PR_{pt}	the production cost per unit of product p in period t
CP_t	the storage capacity of the products of the manufacturer in period t
t_p	the time needed to produce one unit of product p
T_t	total time available for production in period t
α_{ip}	the units of raw material i required to produce one unit of product p
CR_t	the storage capacity of the raw materials of the manufacturer in period t
CS_{ijt}	the supply capacity of raw material i by supplier j in period t
W_i	the cubic volume of raw material i
UV_l	the maximum volume capacity of carrier l
UNV_{lt}	the maximum available number of carrier l in period t
B_{ijkt}	the quantity at which all-unit price break k occurs at supplier j in period t for raw material i
P_{ijkt}	the cost of procuring one unit of raw material i from supplier j at price break level k in period t
h_{it}	the inventory holding cost per unit raw material i during period t
H_{pt}	the inventory holding cost per unit product p during period t
CV_{jlt}	the transportation cost from supplier j by carrier l in period t
M	a sufficiently large number.

Decision variables:

X_{ijklt}	the quantity of raw material i purchased from supplier j at price break level k in period t transported by carrier l
Y_{pt}	the quantity of product type p manufactured in period t
NV_{jlt}	the quantity of carrier l used in period t for supplier j
z_{jt}	a binary variable: 1 if supplier j is chosen in period t , 0 otherwise
v_{jlt}	a binary variable: 1 if carrier l is used in period t for supplier j , 0 otherwise
I_{it}	the inventory level of raw material i at the end of period t
I'_{pt}	the inventory level of product p at the end of period t
b_{ijkt}	a binary variable: 1 if the lot-size of raw material i purchased from supplier j placed in price break level k in period t , 0 otherwise.

3.1. Problem formulation

According to the above parameters, decision variables, and model assumptions, the mathematical model can be formulated as follows:

$$\text{Min } Z = Z_1 + Z_2 + Z_3 + Z_4 + Z_5 \quad (1)$$

$$Z_1 = \sum_i \sum_j \sum_k \sum_t \sum_l X_{ijklt} P_{ijkt} \quad (1a)$$

$$Z_2 = \sum_t \sum_j z_{jt} O_{jt} \quad (1b)$$

$$Z_3 = \sum_t \sum_p Y_{pt} PR_{pt} \quad (1c)$$

$$Z_4 = \sum_t \sum_i I_{it} h_{it} + \sum_t \sum_p I'_{pt} H_{pt} \quad (1d)$$

$$Z_5 = \sum_t \sum_j \sum_l CV_{jlt} NV_{jlt} \quad (1e)$$

Subject to:

$$I'_{pt} = I'_{p(t-1)} + Y_{pt} - D_{pt} \quad \forall p, t > 1 \quad (2)$$

$$\sum_p I'_{pt} \leq CP_t \quad \forall t \quad (3)$$

$$\sum_p Y_{pt} t_p \leq T_t \quad \forall t \quad (4)$$

$$I_{it} = I_{i(t-1)} + \sum_j \sum_k \sum_l X_{ijkl} - \sum_p Y_{pt} \alpha_{it} \quad \forall i, t > 1 \quad (5)$$

$$\sum_i I_{it} \leq CR_t \quad \forall t \quad (6)$$

$$\sum_k \sum_l X_{ijkl} \leq CS_{ijt} Z_{jt} \quad \forall i, j, t \quad (7)$$

$$\sum_l v_{jlt} = z_{jt} \quad \forall j, t \quad (8)$$

$$\sum_i \sum_k X_{ijkl} \leq M v_{jlt} \quad \forall i, j, k, t, l \quad (9)$$

$$\sum_k \sum_i X_{ijkl} W_i \leq NV_{jlt} UV_l + M(1 - v_{jlt}) \quad \forall j, l, t \quad (10)$$

$$\sum_j NV_{jlt} \leq UNV_l \quad \forall l, t \quad (11)$$

$$B_{ij(k-1)t} b_{ijkt} \leq \sum_l X_{ijkl} \leq B_{ijkt} b_{ijkt} \quad \forall i, j, t, k > 1 \quad (12)$$

$$\sum_k b_{ijkt} = z_{jt} \quad \forall i, j, t \quad (13)$$

$$I_{it} \cdot I'_{pt} \geq 0 \quad \forall i, t, p \quad (14)$$

$$X_{ijkl}, Y_{pt}, NV_{jlt} \geq 0 \text{ and integer} \quad \forall i, j, k, t, l, p \quad (15)$$

$$z_{jt}, v_{jlt}, b_{ijkt} \in \{0, 1\} \quad \forall i, j, k, l, t \quad (16)$$

The objective function (1) is to minimize the total cost over the planning horizon. It consists of five terms: (1a) the costs of the purchase, (1b) the ordering costs, (1c) the production costs, (1d) the inventory holding costs for the remaining inventory at the end of each period, which includes raw materials and products holding costs respectively, and (1e) the transportation costs. Constraint (2) represents the inventory balance of products in different periods. Constraint (3) enforces the products' storage capacity per period. Constraint (4) controls the capability of production in each period by time limit production. Constraint (5) computes the amount of raw materials that remain at the end of each period. Constraint (6) determines the raw materials' storage capacity per period. Constraint (7) ensures that raw materials will be provided through suppliers' contracts with the manufacturer. The purchase quantity must not exceed the maximum supplier capacity. Constraint (8) indicates that if the contract is performed by a supplier, a transportation system must also be considered. Constraint (9) assures that if the carrier is not assigned to a supplier, the supplier will not be able to ship the raw materials. Constraint (10) determines the number of carriers used for shipping with respect to its volume. Constraint (11) guarantees that the total number of carriers deployed for transportation will not surpass the maximum number of carriers. Constraints (12-13) are related to the all-unit quantity discount plan. According to these constraints, each lot is purchased from suppliers at a specified price break in the discount interval. Only one price break level which is applied to the lot-size in each period and supplier is considered. Finally, Constraints (14-16) identify the type of different variables.

3.2. Numerical example

To explain the performance of the proposed mathematical model, a numerical example is provided in which the manufacturer wants to purchase three types of raw materials to produce two types of products over a planning horizon of five periods through three potential suppliers. Customers' demands are 20 and 30 for the product number one and two in each period, respectively. The coefficient of raw materials usage for production, the volume of raw materials as well as the capacity of suppliers- which have been considered to be constant through different periods- are given in Table 2. The ordering costs are assumed to be constant in each period, which are 120, 100 and 110 in a monetary unit, respectively. Inventory holding costs for each raw material unit are 2, 3, and 2 in a monetary unit, respectively. Inventory holding costs of products, the time needed to produce one unit of each product and production costs are shown in Table 3. The total production time available in each period is 500 time units. The Storage capacities for the raw materials and products in manufacturer area are 1000 and 100 per period, respectively.

The suppliers' proposed prices for the raw materials considering the price break levels are presented in Table 4. In this example, the discount levels for different periods and raw materials are assumed to be identical.

(Table 2, 3 and 4 should be inserted around here)

Table 5 shows the transportation costs proposed by the suppliers considering the carriers and their maximum capacity volume. Moreover, it displays the maximum number of available carriers, which varies by the period.

(Table 5 should be inserted here)

Table 6 shows the solution obtained from solving the model. As the results show, the optimal solution is to purchase the first raw material (400 units), the second raw material (450 units), and a fraction of the third one (200 units) from the first supplier. The second supplier is selected to supply 300 units of the third raw material, because of the better discount and closer distance of supplier 1, which is obvious in table 6.

(Table 6 should be inserted here)

3.3. Scenarios

For a more comprehensive assessment of the problem parameters, different scenarios have been examined. In this section, we assess two important scenarios to delve into the impact of different quantity discounts and inventory costs on the objective function, while keeping the rest of the parameters at their base value. Three additional scenarios assess the effects of quantity discounts and five further scenarios investigate the inventory costs for the raw materials and products.

3.3.1. The analysis of quantity discounts

As mentioned before, to analyze the effects of quantity discounts, three sub-scenarios are defined and provided in Table 7. In sub-scenario 1, the first supplier does not offer any discounts,

whereas suppliers 2 and 3 offer their previous discounts. As expected, we observe that most of the materials (over 82% of all purchases) are now sourced from suppliers 2 and 3. Thus, manufacturer's purchase from supplier 1 is decreased by about 60%.

In the second sub-scenario, only supplier 3 offers quantity discounts and as a result, a significant percent of the purchases (59%) is made from supplier 3. In addition, because of the proximity of supplier 1, the remaining purchases are sourced from supplier 1.

In sub-scenario 3, suppliers do not offer any discounts, and the selection is made based on other problem criteria. Due to more appropriate conditions offered by the first supplier, all purchases are allocated to it.

(Table 7 should be inserted here)

Fig. 2 illustrates the effects of these variations on the costs. As expected, by eliminating the quantity discount advantage, the total costs as well as the purchasing costs increase, but the costs of ordering and transportation do not show any significant difference. The model strives to find the best trade-off among these cost categories to compensate the increase in the purchasing costs.

(Figure 2 should be inserted here)

3.3.2. The analysis of inventory holding costs

Table 8 illustrates how the amount of purchases is affected by the inventory holding costs. There are five scenarios in which the effects of changes on inventory holding cost for the products and the raw materials are examined. In scenarios 1 and 2 the inventory holding cost for the products is decreased and increased, respectively.

In scenario 1, the reduction in the holding costs of products drives the manufacturer to supply the raw materials and produce the final products less frequently and in larger sizes in order to take advantage of the offered discounts. From Table 8, this practice reduces the total ordering cost, whereas the total inventory of the products at the end of each period will significantly increase. In scenario 2, as expected, the significant increase in the products' inventory holding costs leads to zero inventory level for the products at the end of each period and an increase in the number of orders.

In scenario 3, as the inventory holding costs of the raw materials decreases, the manufacturer supplies the raw materials in larger quantities, which in turn decreases the inventory level of the final products at the end of each time period. This policy will also provide the manufacturer with more opportunities to take advantage of the offered discount privileges. In Scenario 4, as the inventory holding costs of raw materials increases, the objective function increases, whereas the decision variables remain unchanged compared to that of the basic example. The latter is a direct effect of the existing trade-off between the potential discount benefits of ordering in larger quantities versus the rise in the holding costs, which prompts the manufacturer to follow its existing course of ordering and production policies. In Scenario 5, the raw materials undergo a substantial increase in the holding costs to the extent which cannot be offset by the suggested discount benefits. Table 8 shows the change in the order and production policies, so that the inventory only comprises the final products, i.e., no raw material inventory is held at the end of any time period.

In a nutshell, our analyses show that the costs related to raw materials and the final products have consequential influences on supply chain policies, performance, and costs. Therefore, we recommend that supply chain players should acquire more accurate business cost estimations.

(Table 8 should be inserted here)

4. SOLUTION METHOD

In the literature, because of the NP-hardness of lot-sizing in this area, different methods have been used to solve the supplier selection problem. The results of applying GA to a wide variety of supplier selection problems have been very promising among other evolutionary algorithms in both single and multi-objective problems (Liao and Rittscher [10]; Rezaei and Davoodi [13, 20]; Lee et al. [14]; Aliabadi et al. [23]; Gorji et al. [26]). Therefore, encouraged by its noticeable positive features, a GA is proposed in this study to handle large scale problem instances.

4.1. Chromosome representation

In order to solve the problem, a chromosome is designed with four parts. The first part of the chromosome is a $P \times (T-1)$ matrix which is used to calculate the quantity of the leftover products after consumption in each period. The elements of this matrix belong to the standard normal distribution function. Since the premise of the problem is to fulfil customer demand in each period, the available inventory level of the products at every period is determined in this part of the chromosome. The second part of the chromosome is an $I \times (T-1)$ matrix representing the amount of the raw materials left after consumption in each period. The elements of this matrix also have a standard normal distribution. The amount of the raw materials needed in each period is calculated by the following equation:

$$\text{The Demand of raw material } i \text{ needed in period } t = \sum_p Y_{pt} \alpha_{it} \quad \forall p, t > 1 \quad (17)$$

With regard to the values of the second part of the chromosome, the purchasing amount of the raw materials can be calculated by the following equations in each period:

$$\begin{aligned} \text{The Purchasing amount of raw material } i \text{ in period } t \\ &= \text{The demand of raw material } i \text{ in period } t \\ &\times [1 + \text{The elements of matrix } (i,t)] \\ &- \text{The inventory amount of the previous period} \quad (\text{for } t < T) \end{aligned} \quad (18)$$

and,

$$\begin{aligned} \text{The purchasing amounts of raw material } i \text{ in period } T \\ &= \text{The demand of raw material } i \text{ in period } T \\ &- \text{The inventory amount of previous period} \end{aligned} \quad (19)$$

After determining the required purchasing amount of raw materials by the first two parts of the chromosome, the third part determines how to provide the purchase quantities belonging to each supplier by an $i \times j \times t$ matrix with elements taking values from [0,1] and each corresponding to a supplier and a raw material in a period. The elements of this matrix show the supply priority of the specific raw material by the specific supplier in each period. The chromosome numbers are used in compliance with the supplier capacity constraints in a way that the supplier with the highest priority is selected to provide the maximum amount of raw materials. The other suppliers

will be selected in the order of precedence to meet the total demand. In the fourth part of the chromosome, carriers are allocated to each selected supplier. This part is a $j \times l \times t$ matrix with [0,1] element values and is used to cover the carriers' capacity constraints.

4.2. Initialization of the population

There are different approaches to produce the initial population which is the starting point of the algorithm. In this study, we have adopted the random generation of solutions approach to create the initial population. In this way, for each population, a chromosome with the specifications described in the previous subsection is randomly generated. The feasibility conditions that must be assessed after generating each chromosome are:

- Limitation of time availability for production
- Product storage capacity constraints
- Storage capacity constraints for the raw materials.

4.3. Fitness function

Each chromosome is a plausible solution of the problem which is used to calculate the fitness value of the objective function. Since the objective function is based on costs, smaller objective function values generate higher fitness values.

4.4. Selection strategy

The solutions of GA evolve from each generation to the next. Evolution of the population is realized through GA operators such as crossover, mutation and elitism. The hatching process in which we need to select the solutions (chromosomes) from the population, is accomplished through a crossover operation. Different methods have been proposed to select the parents (boltzmann selection, tournament, rank, steady state etc.). The selection method by the Roulette wheel which has been used in this study is among the most popular ones. Moreover, the elitism idea has been implemented on the GA and a percentage of the best chromosomes in the current population will be kept for the next generation.

4.5. Crossover operation

The crossover operator is implemented based on a guide matrix with binary elements. For each chromosome, there is a guide matrix with equal dimensions. To generate new offsprings, the crossover operator is applied to the parents selected by the Roulette wheel approach. If the value of the corresponding element in the guide matrix equals 1, the corresponding values of the parent element would be replaced, otherwise the element is left unchanged. Fig. 3 represents an example of a crossover operation.

(Figure 3 should be inserted here)

4.6. Elitism operation

According to this operator, the chromosomes having the best fitness value in the active generation are automatically carried over to the next. This operator causes further improvement in the efficiency of GA by preventing the loss of good solutions. In other words, the solution quality obtained by the GA will not decrease from one generation to the next.

4.7. Local search

In each iteration of the provided GA, we search to find better neighbourhoods around better solutions in the population. A certain percentage of the best solutions for each generation of the algorithm will be examined in order to find better neighbourhoods. To create a neighbourhood for the algorithm in every part of the chromosome, new elements are calculated through the following equation:

$$\text{New element} = (1 + R) * \text{Old element}$$

In this equation, “R” is a random number with the standard normal distribution. If the new element takes a value more than 1, it will set to 1 and if it takes a value less than zero, it will be considered equal to zero. Searching to find a better neighbourhood stops after finding a better solution. Otherwise, after certain steps and finding no better solution, it stops.

4.8. Mutation operation

In the mutation operation, we randomly switch rows or columns of the chromosome. For the parts of the chromosome that has more than one dimension, this action is applied to each and every dimension. Fig. 4 shows an example of a mutation operation.

(Figure 4 should be inserted here)

4.9. Termination criterion

The most common termination criteria in GA include the fixed number of iterations (or a fixed length of computational time), an arbitrary number of iterations where no further improvement is realized in the objective function, and when the predefined threshold in the objective function value is reached. As for the proposed design, we let the iterations proceed to a specified number; however, the algorithm terminates if no improvement is achieved during 50 consecutive iterations.

4.10. Parameter setting of the proposed GA

We have borrowed the same parameters setting method from Gorji et al [26] and Dai and Zheng [34], based on performing considerable amount of experimental analyses. To find the optimal solution efficiently, some parameters of the GA require to be set appropriately, including the population size, maximum generation number, crossover rate, mutation rate, elitism rate as well as the local search rate. According to this statement, these parameters will be set to achieve the best optimal minimum cost possible in a short time.

- Population size. It is noteworthy that if the population size is huge, it would probably lead to very slow rate of convergence and elude sub-optimal solutions. On the other hand, a small population probably results in a premature convergence and quick rate of convergence. Thus, in the presented article, two choices are available for the population size: 250 and 350 which have moderately resulted in better solutions through extensive experiments having been done on different values for this parameter.
- The maximum generation number. Two options have been applied here: 150 and 200.
- Crossover and mutation rate. Crossover and mutation are the ways to generate new individuals which are mostly used to provide exploitation and exploration, respectively. In this paper, each of them has two choices: 0.85 and 0.93 for crossover, 0.1 and 0.18 for mutation.

- The elitism rate. Elitism guarantees that the solution quality obtained from the GA will not decrease from one generation to the next. In this paper, two choices have been considered which are 0.1 and 0.25.
- The local search rate. Two options have been applied here: 0.1 and 0.2.

As can be seen in Table 9, based on our computational experiments the following combination obtains the best value for the objective function with the shortest time: the population size, maximum generation, crossover rate, mutation rate, elitism rate and the rate of the local search are set at “350”, “150”, “0.93”, “0.1”, “0.25”, and “0.2”, respectively. Of course, these parameters can not guarantee a global optimal solution.

(Table 9 should be inserted here)

5. THE RESULTS OF THE NUMERICAL EXAMPLES

In this section, 10 small and 10 large sample problems are presented to examine the problem in different scales. The experiments were performed on a PC with an Intel dual core i5 CPU at 2.5 GHz and 4 GB of RAM. The results obtained from the GA (coded in MATLAB software) are compared with those of the exact method using LINGO 12. Twenty samples with different dimensions illustrated in Table 10 are considered and the values of the common parameters which are used in these samples are shown in Table 11.

(Table 10 and 11 should be inserted here)

The results which are obtained on small-scale and large-scale problems are presented in Table 12 and 13, respectively. The average run-time is derived from the average of five-time implementations of the algorithm. The gap is obtained through comparing the averages of the best solution values among those five-time implementations with that of the exact method. Fig. 5. demonstrates the values of the objective function over small-scale samples.

(Table 12 and 13 should be inserted here)

As the dimension of the problem increases (samples 11 to 20), the exact method fails to reach the optimal solution in a reasonable time while the proposed GA achieves near-optimal solutions at a fairly short run and with a little variation. It is noteworthy that for samples 19 and 20, the exact method fails to find a feasible solution even in 2,000 seconds and hence, we have terminated it in 4,000 seconds of run time.

(Figure 5 should be inserted here)

Considering Fig. 6, it can be observed that the run times for the GA are more than the exact method for samples 1 to 8, while in the rest of the samples, this trend has changed showing the effectiveness of the presented GA. Fig. 7 shows the rate of change in the objective function value in samples 11 to 20, so that the gap of the solutions is very close which is a persuasive reason to provide proof of the effectiveness of the presented GA.

(Figure 6 and 7 should be inserted here)

6. CONCLUSION

Today, due to the increasing demands and intense competition among product manufacturers, the need for multi-product productions along with an efficient inventory management is felt more than ever. This paper presents a multi-product MILP model for the supplier selection over a multi-period planning horizon. The objectives include the purchase cost of the raw materials from the suppliers, ordering costs, production costs, inventory holding costs of the raw materials and products, as well as the transportation costs. In the problem setting, the manufacturer is allowed to purchase the required raw material through the all-unit quantity discount plan offered by the suppliers which are required to completely satisfy customers' demands. Different raw materials could be shipped by different carriers. The Proposed model seeks to determine which raw materials should be ordered, in what quantities, from which suppliers, by which transportation carriers, and in which periods. To solve the proposed model, an efficient GA has been proposed and twenty small-scale and large-scale samples are presented to show the applicability of the approach. The results are compared with those of the exact method to show the performance of the proposed algorithm.

For the future research, the present model can be further developed by taking into account other assumptions such as the backlog or loss in demand fulfilment, introducing probabilistic and fuzzy parameters. In addition, other meta-heuristics can be employed to improve the quality of solutions and reduce the run time needed to solve the problem. Introducing multiple competing objectives to the problem setting can also serve as an interesting direction for the future research. There are some other related areas that can be inspiring to develop this work such as: sustainable supplier selection, green supplier selection and implementing the MADM approach to cope with new problems regarding various optimization criteria [35-36].
